Abstract. The pH of coastal seawater varies based on several local forcings, such as water circulation, terrestrial inputs, and biological processes, and these forcings are changing along with global climate change. Understanding the mechanism of pH variation in each coastal area is thus important for a realistic future projection that considers changes in these forcings. From 2020 to 2021, we performed parallel year-round observations of pH and related ocean parameters at five stations around the Japanese coast (Miyako Bay, Shizugawa Bay, Kashiwazaki Coast, Hinase Archipelago, and Ohno Strait) to understand the characteristics of short-term pH variations and their forcings. Annual variability (~ 1 standard deviation) of pH and aragonite saturation state (Ω_{ar}) were 0.05–0.09 and 0.25–0.29, respectively, for three

areas with low anthropogenic pressures (Miyako Bay, Kashiwazaki Coast, and Shizugawa Bay), while it increased to 0.16–0.21 and 0.52–0.58, respectively, in two areas with medium anthropogenic pressures (Hinase Archipelago and Ohno Strait in Seto Inland Sea). Statistical assessment of temporal variability at various timescales revealed that most of the annual variabilities in both pH and Ω_{ar} were derived by short-term variation at a timescale of < 10 d, rather than seasonal-scale variation. Our analyses further illustrated that most of the short-term pH variation was caused by biological processes, while both thermodynamic and biological processes equally contributed to the temporal variation in Ω_{ar} . The observed results showed that short-term acidification with $\Omega_{\text{ar}} < 1.5$ occurred occasionally in Miyako and

Shizugawa bays, while it occurred frequently in the Hinase Archipelago and Ohno Strait. Most of such short-term acidified events were related to short-term low-salinity events. Our analyses showed that the amplitude of short-term pH variation was linearly correlated with that of short-term salinity variation, and its regression coefficient at the time of high freshwater input was positively correlated with the nutrient concentration of the main river that flows into the coastal area.

1 Introduction

The ocean is witnessing a reduction in its pH due to anthropogenic CO₂ sequestration both in open oceans (e.g., Bates et al., 2014; Iida et al., 2021; Jiang et al., 2019; Lauvset et al., 2015; Takahashi et al., 2014) and coastal oceans (e.g., Carstensen and Duarte, 2019; Duarte et al., 2013; Hauri et al., 2013; Ishida et al., 2021; Ishizu et al., 2019; Yao et al., 2022). In the coastal ocean, pH shows short time variation caused by several processes such as water mass changes (e.g., Johnson et al., 2013; Ko et al., 2016; Wakita et al., 2021), coastal upwelling (e.g., Barton et al., 2012; Booth et al., 2012; Feely et al., 2008, 2016; Vargas et al., 2015), rivers inputs (e.g., Cai et al., 2017; Fujii et al., 2021; Gomez et al., 2021; Salisbury et al., 2008; Salisbury and Jönsson, 2018), terrestrial nutrients' inputs (e.g., Cai et al., 2011; Guo et al., 2021; Kessouri et al., 2021; Provoost et al., 2010; Sunda and Cai, 2012; Wallace et al., 2014), and various coastal biological processes (e.g., Delille et al., 2009; Lowe et al., 2019; Mongin et al., 2016; Ricart et al., 2021; Yamamoto-Kawai et al., 2021). The amplitude of short-term pH variation often exceeds that of the decadal-scale long-term pH trend, and hence, blurs the signal of anthropogenic CO₂-induced acidification of coastal seawater (e.g., Borges and Gypens, 2010; Duarte et al., 2013; Johnson et al., 2013; Provoost et al., 2010; Salisbury and Jönsson, 2018). Short-term pH variations in coastal waters are important for local ecosystems as they are mostly caused by natural forcings that have been acting before the industrial period, and hence, the local ecosystem is expected to adapt to such short-term pH variations as long as they are natural in terms of timing and amplitude. For example, *Ostrea lurida*, a native oyster in Netarts Bay, Oregon, USA, has adjusted its spawning season before and after the summer upwelling season so that its larvae can avoid low-pH waters (Waldbusser and Salisbury, 2014). Several anthropogenic perturbations, such as changes in land use, sewerage treatment, vanishment of seagrass bed, and modification of coastal topography, can change these forcings, shifting the timing and/or amplitude of natural short-term pH variation (e.g., Hoshiba et al., 2021; Papalexiou and Montanari, 2019). Understanding the present situation as well as the mechanism of short-term pH variation in coastal waters is thus critical for evaluating the risk of acidification in coastal areas.

Japan consists of 14 125 islands distributed in a wide latitudinal range from 20 to 45° N in the western North Pacific, containing diverse coastal environments from coral reefs to seasonal floating sea ice. Japan is a highly developed country and a significant portion of its coastal area has experienced various types of anthropogenic perturbations. The country's Ministry of the Environment (MOE) has conducted regular pH monitoring at over 2000 coastal stations around Japan from the early 1980s until the present, and the obtained data showed significant variability in the multi-decadal pH trend from -0.012 to $+0.009$ yr⁻¹ throughout the stations (Ishizu et al., 2019). The observed range of pH trend within the Japanese coast is equivalent to 85 % of that observed in 83 coastal systems in the world (Carstensen and Duarte, 2019), and this result suggests that the Japanese coastal area can be considered as a “sample shelf” for coastal acidification studies. The MOE monitors pH monthly and seasonally, and several of the pH stations of MOE, especially those in northern areas, lack winter observations (Ishizu et al., 2019). We thus need additional pH observations with a higher time resolution to understand the characteristics of short-term pH variation at a timescale of < 30 d around the Japanese coast to assess its variability and mechanisms. A number of scientists have already started such pH monitoring in coastal stations in Japan (e.g., Christian and Ono, 2019; Fujii et al., 2021, 2023; Ishida et al., 2021; Wakita et al., 2021). However, most of these observations were started recently and a summarization of observed results among these stations has yet to be made. In this study, we carried out the first synthesis effort of such high-resolution pH monitoring stations along coastal areas in Japan that are operated by different founders/programs, by summarizing continuous monitoring data of pH observed during 2020–2021 at five stations around the Japanese coast. Here, we describe and discuss the amplitude of pH variation in each timescale, similarity, and dissimilarity in the characteristics of variation, and their forcings.

2 Observations and settings of study areas

Hydrographic monitoring, including pH monitoring, was performed from 2020 to 2021 at the following five stations around the coast of Japan: Miyako Bay, Shizugawa Bay, Kashiwazaki Coast, Hinase Archipelago, and Ohno Strait (Fig. 1). Miyako Bay and Kashiwazaki Coast were selected to represent coastal environment with relatively low anthropogenic nutrient loadings, while the other three stations were selected from major farming areas of pacific oyster. The detailed settings of the areas and observation procedures are described in the following sections.

2.1 Miyako Bay

Miyako Bay is located in the northern part of Honshu Island facing the western North Pacific, with a bay area of 24 km²

Figure 1. Map of the five study stations along the coast of Japan.

and a 4.8 km wide bay mouth (Fig. 2a). The outer bay area is usually occupied by temperate western North Pacific water, which brings enough nutrients in winter to support seaweed farms in the coastal area (Kakehi et al., 2018). Additional nutrients to the bay are provided by three rivers: Hei, Tsugaruishi, and Tashiro (25.8 , 5.16 , and $3.78 \text{ m}^3 \text{ s}^{-1}$, respectively, for annual average flow rate; Okada et al., 2014), although the quantity of nutrients input by the rivers are limited to low levels (57 , 11 , and 8 tN yr^{-1} for Hei, Tsugaruishi, and Tashiro rivers, respectively; Bernardo et al., 2023). With a population of 60 000 residents within the hinterland, Miyako Bay has maintained good water quality with $1\text{--}2 \text{ mg L}^{-1}$ of chemical oxygen demand (MOE, 2022). While kelp beds are well developed near the shoreline, wakame seaweed (*Undaria pinnatifida*) farmyards are developed in the middle of the bay.

The monitoring site was located in front of the Miyako Field Station of the Japan Fisheries Research and Education Agency, which is located north of the bay mouth ($141^\circ 58' 5'' \text{ E}$ and $39^\circ 41' 28'' \text{ N}$; Fig. 2). This area frequently encounters severe winter storms, so we set the monitoring station in the settling tank ($3.6 \times 2.8 \times 5.4 \text{ m}$) of the field station, in which coastal water is continuously pumped from the water intake located 200 m off the coastline and 1–3 m in depth (Fig. 2). Sensors for pH (SPS-14; Kimoto Electric), dissolved oxygen (DO) (AROW2; JFE Advantech), and salinity/water temperature (ACTW; JFE Advantech) were then moored at a depth of 1 m in the settling tank. Mechanical precision of each sensor is $\pm 0.003 \text{ pH units}$ for pH, $\pm 2\%$ for DO, ± 0.008 for salinity, and $\pm 0.01^\circ \text{ C}$ for water temperature, respectively. The difference in pH between water intake and settling tank was measured for two

Figure 2. Map of Miyako Bay with the location of the station (black circle). Overlaid map shows detailed structure of the station. Gray square and black triangle represent locations of settling tank and water intake, respectively.

weeks during the monitoring period, and it was confirmed that the difference in pH between the water intake and settling tank was $< 0.006 \text{ pH units}$. The sampling frequency of each sensor was set to 1 h. All sensors were replaced every 2 months because of the limitation of batteries, and the DO sensor was calibrated by air-saturated pure water and sodium sulfite solution, while the pH sensor was calibrated against tris(hydroxymethyl)aminomethane and 2-amino-2-methyl-1-propanol-buffered artificial seawaters provided by FUJIFILM Wako Pure Chemical Corporation (cat. no. 017-28191 and 010-28181, respectively) at the beginning of each deployment. Along with these measurements, discrete water samples were taken from the tank at a depth of 1 m using a 1.5 L Niskin bottle every week. Subsamples for salinity, nutrients, dissolved inorganic carbon (DIC), and total alkalinity (TA) were then taken and stored. Salinity and nutrients were measured at the Yokohama Laboratory of the Japan Fisheries Research and Education Agency using a salinometer (8400 B; Guildline Instruments) and continuous flow analyzer (QuAatro 39; Seal Analytical), respectively, while DIC and TA were measured at the Mutsu Institute for Oceanography of the Japan Agency for Marine-Earth Science and Technology (MIO-JAMSTEC) using a carbon coulometer (UIC CM 5012 with Nippon ANS model 3000A) and an open-

cell titrator (Kimoto Electric ATT-15) calibrated against the seawater reference materials provided by KANSO Corporation (Wakita et al., 2021). Measurement precision was $\pm 1 \mu\text{mol kg}^{-1}$ for both DIC and TA. The pH of the seawater at the time of each sampling ($\text{pH}_{\text{discrete}}$) was calculated from DIC and TA using the CO2sys program v2.1 (Pierrot et al., 2006), with the settings of Lueker et al. (2000) for the dissociation constant of carbonate, Dickson (1990) for the dissociation constant of bisulfate, and Lee et al. (2010) for the aqueous boron concentration. The drift of the pH sensor during deployment was corrected based on the difference between $\text{pH}_{\text{discrete}}$ and the pH measured by the sensor. The relationship between the measured TA and salinity was evaluated as a linear function, and the time series of TA throughout the sensor deployment was calculated based on the salinity–TA relationship. The saturation states of aragonite (Ω_{ar}) were then calculated from water temperature, salinity, nutrient concentrations, DIC, and TA using the CO2sys program. This monitoring program, founded by the Study on Biological Effects of Acidification and Hypoxia (BEACH) of the Environment Research and Technology Development Fund of the Environmental Restoration and Conservation Agency, started on 1 July 2020 and ended on 21 September 2021.

2.2 Kashiwazaki Coast

Kashiwazaki City is located at the center of Honshu Island facing the Sea of Japan. Its coastline has little flexure, with the periodic occurrence of shallow sandy beaches and small rocky reefs (Fig. 3a). While benthic biomass is quite low in sandy beach coastal areas, local *Sargassum* seaweed beds are formed off rocky reefs. The low-nutrient Tsushima Warm Current flows throughout the year off the narrow band of low-salinity coastal water (Niigata Prefectural Institute for Fisheries and Oceanography, 1998). Kashiwazaki City has a population of 79 000 with a cultivated land area of 4890 ha (mainly rice paddy fields) and ~ 200 plants of manufacturing industries. Sewage waters from these civil activities are released into coastal areas via two small rivers, Sabaishi and Ukawa, which bring low salinity and nutrients. The quality of off-Kashiwazaki coastal waters has been well maintained, with a chemical oxygen demand of $< 2 \text{ mg L}^{-1}$ (MOE, 2022). However, 30 years of monitoring by the Marine Ecology Research Institute shows that the pH of off-Kashiwazaki coastal water has decreased at a rate of -0.003 yr^{-1} because of the increase in water temperature and concentration of atmospheric CO_2 (Ishida et al., 2021).

Similar to the Miyako site, sensors for pH, DO, and salinity/water temperature were set within the water tank (3000 L), to which coastal water was continuously pumped from the water intake set in front of the Marine Ecology Research Institute ($138^\circ 35' 24'' \text{ E}$ and $37^\circ 25' 30'' \text{ N}$; Fig. 3b). The settings of each sensor, water sampling, and measurements were the same as those of the Miyako site. This monitoring program,

Figure 3. Panel (a) shows a detailed map of Kashiwazaki Coast with the location of the station (black circle), and (b) shows locations of water intake and the settling tank in Kashiwazaki Observatory.

also founded by BEACH, started on 16 July 2020 and ended on 24 August 2021.

2.3 Shizugawa Bay

Shizugawa Bay is located $\sim 100 \text{ km}$ south of Miyako Bay, with a bay area of 46.8 km^2 and a 6.6 km wide bay mouth (Fig. 4). The Oyashio-oriented cold-water and Kuroshio-oriented warm-water masses intermittently occupy the outer bay, and the former water brings high quantities of nutrients to this bay in winter, similar to that in the Miyako Bay. The large Kitakami River (water transport of $390 \text{ m}^3 \text{ s}^{-1}$), flows out to the sea south of Shizugawa Bay, bringing nutrients of $6 \times 10^3 \text{ tN yr}^{-1}$ to the coastal area (Sugimura et al., 2015). In addition, 10 small rivers flow directly into the bay and the total nutrient flux provided by these rivers was estimated at 270 tN yr^{-1} (Yamamoto et al., 2018). Shizugawa Bay has been widely used for the aquaculture industry, especially for culturing Pacific oysters and silver salmon. Historically, the extent of aquaculture utilization occasionally becomes too heavy, resulting in the emergence of low-oxygen deep waters in the bay caused by the degradation of organic materials derived from aquaculture. After the Great East Japan Earthquake in 2011, oyster farmers in Shizugawa Bay decided to

Figure 4. Detailed map of Shizugawa Bay with the location of the station. The white circles represent stations installed by the Ocean Acidification Adaptation Project and the black circle represents the location of station S3 used in this study.

reduce the number of their oyster rafts to one-third of what they had before the earthquake to reduce the environmental impact of aquaculture on the bay ecosystem, which was on the way to recovery from the tsunami disaster. As a result, the DO of the bottom water in the bay showed a remarkable increase by $> 1 \text{ mg L}^{-1}$ (Yamamoto et al., 2017).

Since 2020, hydrographic conditions, including pH, have been observed at four stations within Shizugawa Bay (Fig. 4) by the Ocean Acidification Adaptation Project (OAAP) founded by the Nippon Foundation (Fujii et al., 2023). Detailed settings of the observations are described in Fujii et al. (2023), and here, we reproduce its brief outline: sensors for water temperature, salinity, DO, and pH were set at a depth of 1 m in each station to collect data at a temporal resolution of 1 h. Water samples for salinity, nutrients, DIC, and TA were taken from each station monthly, and the sampling interval was enhanced to every 15 d during summer. Salinity, nutrients, DIC, and TA were measured by the same methods as for the Miyako site, although measurements were made at the Kesen-numa Laboratory of Miyagi Prefectural Institute for Fisheries Sciences and MIO-JAMSTEC for nutrients and other properties, respectively. Similar to the Miyako site, $\text{pH}_{\text{discrete}}$ was calculated from DIC and TA and

used for the drift correction of the pH sensors. The time series of TA throughout the sensor deployment was also calculated based on the observed TA–salinity relationship. In this study, we used data from Station S3 (Fig. 4) as a representative of Shizugawa Bay, as this station is located in oyster farming areas, the largest aquaculture industry, which is the largest source of organic carbon in this bay. The measurement of water temperature, salinity, and pH was started on 20 August 2020 and that of DO on 27 April 2021. All parameters are continuously measured to date; however, we use data from August 2020 to December 2021 to maintain synchronicity with data of other stations.

2.4 Hinase Archipelago

The Seto Inland Sea is the largest inner sea in Japan ($\sim 2.32 \times 10^4 \text{ km}^2$) surrounded by the Honshu, Shikoku, and Kyushu Islands, and the Hinase Archipelago is located in the middle of the Seto Inland Sea. This area consists of four major waterways and many small canals divided by Honshu Island and eight other small islands with a water depth of $\sim 6 \text{ m}$ (Fig. 5). The Seto Inland Sea is a moderately eutrophic area, receiving $53.0 \text{ km}^3 \text{ yr}^{-1}$ of freshwater and $1.41 \times 10^5 \text{ tN yr}^{-1}$ of nitrate from the surrounding lands (Higashi et al., 2018; Nishijima, 2018). The water exchange rate between the Seto Inland Sea and the outer North Pacific is also high (residence time of ~ 8 months; Yanagi and Ishii, 2004), and as a result, the nutrient concentration of surface water in the Seto Inland Sea is maintained at a moderate level ($\sim 0.4 \mu\text{M}$ of DIN near the Hinase Archipelago; Tsukamoto and Yanagi, 1998). Historically, nutrient loading was the highest in the 1980s ($\sim 2.35 \times 10^5 \text{ tN yr}^{-1}$; Nishijima, 2018). While the long-standing efforts of local communities succeeded in reducing it to the current level, significant quantities of organic nutrients still remained in the bottom sediment, creating local internal sources of nutrients in the Seto Inland Sea (e.g., Yamamoto et al., 2021). Although there is no large point source of nutrients, such as chemical plants, near the Hinase Archipelago, this area also receives nutrients from the Bizen city, which has a population of 36 000 residents. The Chikusa River, with an average flow rate of $33.5 \text{ m}^3 \text{ s}^{-1}$, flows in the eastern edge of this area, while several other small streams provide additional freshwater. The coastal area of the southern Hinase Archipelago is filled with eelgrass beds, while the northern coastal areas are partially filled with artificial shorelines, such as port facilities and breakwaters. Oyster aquaculture is widely used in open water areas. The OAAP also launched four stations in this area (Fig. 5). Settings of sensors, water sampling, and its measurements were the same as those of Shizugawa Bay, with the exception that nutrient measurements were done by the Okayama Prefectural Institute of Fisheries Sciences (see Fujii et al., 2023 for details). In this study, we used data from Station H2 (Fig. 5) to represent the Hinase Archipelago, as this station is located in the center of oyster farming areas.

Figure 5. Detailed map of Hinase Archipelago with the location of the station. The white circles represent stations installed by the Ocean Acidification Adaptation Project and the black circle represents the location of station H2 used in this study.

Measurements of water temperature, salinity, and pH were started on 29 August 2020, while measurements of DO were started on 10 June 2021. All parameters are continuously measured to date; however, we use data from August 2020 to December 2021.

2.5 Ohno Strait

Ohno Strait is the small strait between Honshu and Miyajima islands, which are located at the southern boundary of Hiroshima Bay in the western Seto Inland Sea (Fig. 6). As part of the Seto Inland Sea, the surface water surrounding Ohno Strait is moderately eutrophic ($\sim 2 \mu\text{M}$ of DIN; Tsukamoto and Yanagi, 1998), although it is slightly lower than the Hinase Archipelago, reflecting an east–west gradient of surface nutrient concentration. The Ohta River, which flows through Hiroshima city with a population of 1.2 million, adds $1.93 \times 10^3 \text{ tN yr}^{-1}$ of nitrogen into Hiroshima Bay (Yamamoto et al., 2002). Part of the Ohta River water plume flows into the Ohno Strait (Abo and Onitsuka, 2019), providing nutrients to the surface layer of this strait. Industrial areas with a population of 115 000 are developed along the western coast of this strait, providing another nutrient source to this area. The strait itself is lightly used for oyster farming and the bottom sediment in the strait is mainly filled by silt and shell fragments.

The monitoring station was launched in the experimental raft off the Hatsukaichi Field Station of the Japan Fisheries Research and Education Agency, with a water depth of 3–6 m depending on the tide. A set of sensors (SPS-14 for pH, Kimoto Electric; AROW2 for DO, JFE Advantech; and ACTW for salinity/water temperature, JFE Advantech) were fixed from the raft at a depth of 1 m, and each parameter was measured at an interval of 1 h. The methods and frequencies for sensor calibration and discrete water sampling were the same as those of the Miyako site. This station was launched

Figure 6. Detailed map of Ohno Strait with the location of the station (black circle).

on 22 June 2021 by the OAAP and is continuing to operate to date; however, we used data from June 2021 to December 2021.

3 Results

3.1 Temporal variation in water temperature, salinity, and DO

Figure 7 shows the time series of water temperature, salinity, and DO at the five stations. All stations showed similar seasonal variations in water temperature, with the highest and lowest temperatures in July and February, respectively (Fig. 7a). The seasonal amplitude was the largest in Hinase and the smallest in Miyako. At all stations, water temperature showed significant day-to-day variation with a timescale of $< 10 \text{ d}$ and also diurnal variations. We discuss this further in Sect. 4.1.

Time series of salinity in Shizugawa, Hinase, and Ohno show similar patterns of seasonal variation, low in summer/autumn and high in winter (Fig. 7b), suggesting that the main source of freshwater in these areas are rainfall events (during the rainy season in June–July and typhoon season in August–October). In contrast, in Kashiwazaki, salinity is high in summer and low in winter, suggesting that the main freshwater source in this area is snowfall in winter. The salinity of the Miyako site shows two low-salinity peaks, one in spring and the other in autumn, suggesting that this area is affected by both snowmelt waters and typhoon events (JFA, 2004). In Miyako, Shizugawa, Hinase, and Ohno, where the freshwater input is significant in summer/autumn, salinity frequently showed short-term drawdown that is synchronized with local rainfall events. The amplitude of sporadic

Figure 7. Time series of (a) water temperature, (b) salinity, and (c) DO at the five stations. Legends of color plots are the same for all panels as shown in (b).

salinity drawdown was extremely large in Hinase and Ohno, where the surface salinity temporally reached to less than 10 (Fig. 7b). Amplitude of seasonal annual variation in these two areas reaches over 25, which corresponds to the largest annual salinity amplitude among the world's 83 stations collected in Carstensen and Duarte (2019). We discuss the effect of these short-term low-salinity events on pH in Sect. 4.3.

DO showed similar patterns of seasonal variation: low in summer and high in winter, although the durations were short in Hinase and Ohno (Fig. 7c). This pattern suggests that the seasonal variation in DO is mainly driven by variation in oxygen solubility induced by water temperature rather than biological processes (see Sect. 4.2 for more details). This seasonal variation overlaps with day-to-day variation with a duration of ~ 10 d, and the amplitude of such day-to-day variation is especially significant in Hinase and Ohno in summer and autumn. Because of this short-term day-to-day variation, DO in Hinase and Ohno were occasionally below $150 \mu\text{mol kg}^{-1}$ in summer and autumn, indicating that water

conditions in these two areas occasionally become significantly undersaturated in DO, even in surface waters.

3.2 Temporal variation in pH

Figure 8a shows the time series of pH after drift correction at five stations. (Hereafter, all pH values are reported in total scale in this paper.) Although the mechanistic precision of the pH sensor is ± 0.003 pH units, the uncertainty of the pH value measured by the glass electrode is mainly controlled by the precision of its drift correction. In the case of Miyako, where drift correction was performed weekly, we set two pH sensors in the same settling tank for 2 weeks to evaluate the reliability of pH data after the drift correction process. Values of pH obtained from the two sensors matched with that of 2 standard deviations (SD) of ± 0.010 pH units, and we used this value as the uncertainty of pH values obtained at Miyako, Kashiwazaki, and Ohno stations. In Shizugawa and Hinase, drift corrections were made at longer intervals, and Fujii et al. (2023) evaluated the uncertainty of pH at these two stations at ± 0.015 pH units. Figure 8a shows significant daily fluctuations far higher than these pH uncertainties. The diurnal amplitude was the largest in winter in Shizugawa Bay, where the difference in pH between day and night exceeded 0.8 pH units. Large diurnal variations in pH and/or $p\text{CO}_2$ are often measured in shallow coastal ecosystems (e.g., Fujii et al., 2021; Ricart et al., 2021; Waldbusser et al., 2014). In most cases, large diurnal pH variation is observed in summer, and the largest diurnal amplitude of pH in winter has rarely been reported. Such patterns raise the possibility of biofouling in pH sensors (e.g., Venkatesan et al., 2017), although visual inspection at the time of sensor exchange did not show significant adherence of biomes during winter. However, the detailed pH variation in each day (Fig. 8b) showed that during the night it was relatively low and constant, even during significant diurnal variation. This is probably because the organic material produced by the fouling biomes during the day had settled down from the sensors, and hence, the effect of the decomposition of organic materials during the night remained low even in the large diurnal variation period. We do not further discuss diurnal variations of pH, as we do not have definite evidence for the effect of biofouling in winter in Shizugawa Bay. We alternatively calculated the daily minimum pH (pH_{min}), which is usually observed at night, and analyzed the day-to-day variation in pH_{min} at various timescales (Fig. 8c). Several rearing experiments have suggested that coastal organisms are affected by pH_{min} rather than the daily average pH (e.g., Onitsuka et al., 2018); therefore, the daily variation in pH_{min} was analyzed instead of pH.

pH_{min} showed a similar pattern of seasonal variations at all five stations, with high values in winter and low values in summer/autumn (Fig. 8c). Seasonal amplitude was the smallest in Miyako and the largest in Hinase and Ohno (Fig. 7a). In Hinase and Ohno, the annual range of pH_{min} variation reached over 1.1 pH units, which was larger than

Figure 8. Panel (a) shows time series of pH in each station. Panel (b) shows an example of detailed pH time series. Data in Shizugawa Bay from 2 to 9 February 2021 are presented here. Panel (c) shows time series of pH_{min} in each station. Legends of color plots are the same for all panels as shown in (c).

that of 83 stations around the world listed in Carstensen and Duarte (2019) except for the Baltic Sea. This seasonal variation overlapped with the short-term drawdown event of pH_{min}, which was frequently observed in summer/autumn. The timing of such events was synchronized with that of short-term low-salinity events (Fig. 7b). This result indicates that either rainfall or increased river flow causes several short-term processes in these coastal areas, causing short-term variation in pH.

3.3 Relationship between TA and salinity

Figure 9 shows the observed relationship between TA and salinity based on discrete water samples obtained at each station. TA in Miyako, Kashiwazaki, and Shizugawa varied in a narrow range between 2222 and 2236 $\mu\text{mol kg}^{-1}$ at a salinity of 33.5, which is approximately equal to that in the surface waters of the western North Pacific in the corresponding latitudinal range (Takatani et al., 2014). This similarity

Figure 9. Salinity–TA relationship based on discrete water samples obtained from (a) Miyako, (b) Kashiwazaki, (c) Shizugawa, (d) Hinase, and (e) Ohno stations. Regression equations are provided below the x axes.

of TA range indicates that coastal waters in these three areas are occasionally not significantly different from their open water sources when salinity is satisfactorily high (~ 33.5). In contrast, in Hinase and Ohno, we obtained TA of 2222 and 2182 $\mu\text{mol kg}^{-1}$, respectively, if we extended their regression equation to a salinity of 34.0. These values again fit with those of Kuroshio waters (Takatani et al., 2014), reflecting that the ultimate source water for the Seto Inland Sea is Kuroshio. It is noteworthy that the maximum salinity values observed in Hinase and Ohno were 31.67 and 31.43, respectively (Fig. 7b). These results indicate that the open waters of the Hinase and Ohno areas are already diluted from their ultimate source (i.e., Kuroshio water), and hence, have already witnessed several modifications through coastal processes within the Seto Inland Sea.

The freshwater endmember in each regression line represents the TA of the main freshwater source in each area, although the absence of a low-salinity data point leads to a

high uncertainty in estimating the endmember. Table 1 describes the list of TA at the mouth of the major freshwater inflow in each coastal area. In most study areas, the calculated freshwater endmember of TA- S regressions agreed with the observed TA of one of the freshwater sources (Table 1), indicating that non-dilution/concentration changes in TA (Jiang et al., 2014) were relatively small in these areas, and by comparing these values with the freshwater endmember calculated from Fig. 9, we can speculate which river was the actual major freshwater source for each area. For the Miyako station, which is located at the northern edge of Miyako Bay, the Tashiro River becomes a major controller of salinity because of its proximity to the station. Two small rivers are neighboring the Kashiwazaki site and both rivers can act as salinity controllers for this site based on TA. Interestingly, all small rivers that flow into Shizugawa Bay had far higher TA than the calculated freshwater endmember, reflecting the existence of limestone areas in their basin. Rather, the TA of Kitakami River, despite flowing into a different bay south of Shizugawa, fitted with that of the freshwater endmember, suggesting that this river is the main source of freshwater for Station S3 because of its large flow rate. In the Hinase Archipelago, all surrounding rivers had similar TA, and hence, we cannot determine which rivers are the main freshwater sources for Station H2. The freshwater endmember calculated in Ohno Strait was significantly higher than the TA of its neighboring large river (Ohta River), suggesting an additional contribution from small rivers directly facing this strait.

3.4 Temporal variation in parameters derived from $\text{pH}_{\min}$ and TA

Based on the regression equation obtained from Fig. 9, we calculated the time series of TA from the time series of salinity at each station (Fig. 10a). We then calculated the time series of DIC, $p\text{CO}_2$, Ω_{ar} , and Ω_{ca} from $\text{pH}_{\min}$ and TA, and here, we show the results of $p\text{CO}_2$ and Ω_{ar} in Fig. 10b and c. In this calculation we used time series of $\text{pH}_{\min}$ and TA estimated from salinity, and uncertainty of these parameters were of the order of ± 0.010 pH units and $\pm 20 \mu\text{mol kg}^{-1}$ for $\text{pH}_{\min}$ and TA, respectively (see Sects. 3.2 and 3.3 for details). Uncertainty of derived parameters by using these values were estimated by using CO2sys program as $\pm 15 \mu\text{atm}$ and ± 0.07 for $p\text{CO}_2$ and Ω_{ar} , respectively.

Since TA was calculated as a linear equation of salinity, it was expected to have a resemblance between the TA and salinity patterns (Fig. 10a). Sporadic decreases in TA corresponding to low-salinity events in Hinase and Ohno were noticeable. Water with low TA has low buffer capacity, and hence, it has particularly high risks of low pH and high $p\text{CO}_2$ (e.g., Carstensen and Duarte, 2019; Salisbury et al., 2008). Figure 10b shows an appearance of such risk, extremely high $p\text{CO}_2$ over $1500 \mu\text{atm}$ during the low-salinity period in Hinase and Ohno. The annually averaged $p\text{CO}_2$ values

Figure 10. Time series of (a) TA, (b) $p\text{CO}_2$, and (c) Ω_{ar} at the five stations. Legends of color plots are the same for all panels as shown in (a). The solid line in (b) represents the $p\text{CO}_2$ value in equilibrium with the present atmospheric CO_2 concentration of 416 ppm. The dashed line in (c) represents the experimentally obtained threshold of the ocean acidification effect for the larvae of Pacific oyster *Crassostrea gigas* ($\Omega_{\text{ar}} = 1.5$; Waldbusser et al., 2015).

were 404, 450, 393, 589, and $621 \mu\text{atm}$ for Miyako, Kashiwazaki, Shizugawa, Hinase, and Ohno, respectively, showing that surface waters are in equilibrium with or even higher than current atmospheric concentration of CO_2 (416 ppm at 2021; WDCGG, 2024). Generally, estuary areas tend to become sources of atmospheric CO_2 , while “open” coastal areas, such as marginal seas, continental shelves, and large bays, tend to become sinks of atmospheric CO_2 (e.g., Borges et al., 2005; Kubo et al., 2017; Laruelle et al., 2010; Tokoro et al., 2020). Typically, terrestrial input of organic matter from rivers is mostly decomposed in estuaries, causing high $p\text{CO}_2$ and low pH, as well as a high nutrient flux to the outer estuary. In an “open” coastal area, nutrients transported from the estuary activate high primary production, which causes low $p\text{CO}_2$ and high pH in surface waters. The Seto Inland Sea itself is considered a sink of atmospheric CO_2 (e.g., Tokoro et

Table 1. Total alkalinity (TA) of freshwater sources in each coastal area, with calculated TA of freshwater endmember from the salinity–TA relationship (see Fig. 9). Uncertainty terms of freshwater endmember was calculated as standard error of sal = 0 intercept in least squares fitting.

Area	Freshwater endmem- ber of TA from Fig. 9	Freshwater source in each area	TA in each freshwater source
Miyako Bay	158 ± 84 μmol kg ^{−1}	Hei River	415 μmol kg ^{−1} ^a
		Tsugaruishi River	482 μmol kg ^{−1} ^b
		Tashiro River	142 μmol kg ^{−1} ^b
Kashiwazaki Coast	735 ± 132 μmol kg ^{−1}	Sabaishi River	845 μmol kg ^{−1} ^b
		Ukawa River	655 μmol kg ^{−1} ^b
Shizugawa Bay	280 ± 172 μmol kg ^{−1}	Kitakami River	351 μmol kg ^{−1} ^a
		Small rivers in Shizu- gawa Bay	725–1108 μmol kg ^{−1} ^b
Hinase Archipelago	516 ± 169 μmol kg ^{−1}	Chikusa River	525 μmol kg ^{−1} ^a
		Small rivers in the Archipelago	495–640 μmol kg ^{−1} ^b

^a Values from Kobayashi (1960). ^b Measured in this study.

al., 2020), and hence, it can be treated as an open coastal area. Our results indicate that despite the high distance from the large river mouth, both Hinase Archipelago and Ohno Strait can be classified as “estuaries”, or at least as areas that receive a significant quantity of particulate organic matter from land.

The Ω_{ar} was high in summer and low in winter in Miyako, Kashiwazaki, and Shizugawa (Fig. 10c), showing an opposite pattern to the seasonal variation in pH_{min} . This was due to the large seasonal variation in the solubility of aragonite induced by the seasonal change in water temperature (see Sect. 4.2). In contrast, in Hinase and Ohno, the amplitude of seasonal variation in pH was large enough to overcome seasonal variation in aragonite solubility, and as a result, Ω_{ar} changed to show a seasonal maximum in winter and a seasonal minimum in summer. Short-term variation in Ω_{ar} linked to that of salinity also overlapped with seasonal scale variation, and as a result, significantly low Ω_{ar} conditions were frequently observed in Hinase and Ohno. Fujii et al. (2023) described that during summer–autumn in the Hinase Archipelago, Ω_{ar} occasionally falls below the threshold level of the larvae of the Pacific oyster *Crassostrea gigas*, with the effect of ocean acidification (OA) becoming detectable in the rearing experiment ($\sim \Omega_{\text{ar}} = 1.5$; Waldbusser et al., 2015). This study showed that the situation was almost the same in Ohno Strait (Fig. 10c). It should be highlighted that Fujii et al. (2023) also noted that actual damaged larvae were not detected based on microscopic inspection of Hinase ($n = 1062$). The rearing experiment of Waldbusser et al. (2015) was conducted on the Oregon coast (USA), where *C. gigas* is non-native.

Therefore, it is not unrealistic that there is a difference in the tolerance for OA between the local population of Oregon and Seto Inland Sea, the latter being the native habitat of *C. gigas*. Kurihara et al. (2007) examined the effect of low pH in the Seto Inland Sea population of *C. gigas*, and found that the larvae of this population are affected by OA at a pH of 7.4 (National Bureau of Standards (NBS) scale). This threshold approximately corresponds to a pH of 7.27 in the total scale, and in this case, larvae of Pacific oysters are considered to be safe in most seasons both in Hinase and Ohno (Fig. 8c). In the experiment by Kurihara et al. (2007), the rearing experiment was occupied only at the control (pH of 8.2 in the NBS scale) and acidified (pH of 7.4 in the NBS scale) conditions, and hence, a true threshold for the Seto Inland Sea Pacific oyster population can exist between a pH of 7.27 and 8.07. We thus need further studies, including new rearing experiments, to determine why Pacific oyster larvae are still safe in the present Hinase Archipelago.

A low Ω_{ar} level (below 1.5) was also detected in Shizugawa Bay (Fig. 10c; Table 2; Fujii et al., 2023) and Miyako Bay (Fig. 10c; Table 2), but its duration was only 4 d and 1 d, respectively, throughout the study period. In Kashiwazaki, Ω_{ar} was above this level throughout the observation period. Other calcifiers that are important for fisheries around the Japanese coast, such as Ezo abalone (*Haliotis discus hannai*) and short-spined sea urchin (*Strongylocentrotus intermedius*), have lower Ω_{ar} thresholds than that of Pacific oyster: 1.1 for *H. discus hannai* (Onitsuka et al., 2018) and 1.12 for *S. intermedius* (Zhan et al., 2016). Therefore, Shizugawa Bay, Miyako Bay, and Kashiwazaki Coast have a low risk of

OA, at least from the viewpoint of fisheries. However, note that we have investigated only a few marine species so far, and there may be many unknown species that are vulnerable to low pH/low Ω_{ar} conditions. We must enhance our knowledge of biological responses according to species, especially for those with low economic importance, such that we can evaluate the total risk posed by OA to the coastal ecosystem.

4 Discussion

4.1 Quantification of short-term variability in properties of water

We focused on short-term variations of pH and related parameters with timescales shorter than 1 month, which cannot be detected by regular MOE monitoring based on water sampling. To assess this quantitatively, we calculated the SD of each parameter at different timescales (annual, monthly, and 10 d). See Appendix A for the abbreviation of each calculated SDs.

The results are listed in Table 2. As shown in Figs. 7 and 9, both the amplitude and frequency of short-term variation differed significantly among the seasons for almost all parameters. To determine seasonal differences in the extent of short-term variation, $\text{avgSD}_{10}^{\text{m}}$ in each month is listed in Table 3.

The $\text{SD}_{\text{a(m)}}$ of water temperature was in the range of 3.9–7.2, and this was almost the same as that of SD_{a} (Table 2). This implies that a large timescale variation of over 1 month (e.g., seasonal scale) was the main component of observed annual temporal variation (Fig. 7a). The $\text{avgSD}_{\text{m}}^{\text{a}}$ of water temperature (0.9–1.5) was < 25 % of the SD_{a} (3.9–7.2), and the $\text{avgSD}_{10}^{\text{a}}$ (0.5–0.8) was approximately half of $\text{avgSD}_{\text{m}}^{\text{a}}$ in each area (Table 2). In the case of salinity, on the other hand, $\text{SD}_{\text{a(m)}}$ (0.34–3.91) was about 70 % of SD_{a} (0.63–5.34), indicating that variations with a shorter timescale than 1 month contribute some parts of annual variation in the case of salinity. The $\text{avgSD}_{\text{m}}^{\text{a}}$ of salinity (0.33–2.37) was approximately half of the SD_{a} (0.66–5.34) in each area, and $\text{avgSD}_{10}^{\text{a}}$ (0.26–1.40) was approximately two-thirds of $\text{avgSD}_{\text{m}}^{\text{a}}$. Seasonal variability of $\text{avgSD}_{10}^{\text{m}}$ was also higher than that of water temperature (Table 3), and as a result, $\text{avgSD}_{10}^{\text{m}}$ of salinity occasionally exceeded the SD_{a} in several months. Interestingly, $\text{avgSD}_{10}^{\text{a}}$ and $\text{avgSD}_{\text{m}}^{\text{a}}$ were almost the same in Miyako, Kashiwazaki, and Shizugawa (Table 2), and the $\text{maxSD}_{10}^{\text{a}}$ for salinity was higher than the $\text{maxSD}_{\text{m}}^{\text{a}}$. Such a result can be attributed to the perturbation of salinity that mainly occurs within the timescale of 10 d, and monthly SD of salinity is essentially determined by the amplitude and frequency of 10 d salinity variation included within that month. Although the $\text{avgSD}_{10}^{\text{a}}$ of salinity was lower than the $\text{avgSD}_{\text{m}}^{\text{a}}$ in Hinase and Ohno, the $\text{maxSD}_{10}^{\text{a}}$ was still higher than the $\text{maxSD}_{\text{m}}^{\text{a}}$, indicating that the 10 d variation is also an influential component of monthly variation in these two areas.

The relative contribution of short-term variation to annual variability for other parameters varied between the above two extremes (water temperature and salinity). In the cases of DO and pH, $\text{SD}_{\text{a(m)}}$ was on the same level with SD_{a} in Miyako, Kashiwazaki, and Shizugawa, but it declined to about 80 % of SD_{a} in Hinase and Ohno. The $\text{avgSD}_{\text{m}}^{\text{a}}$ was around 25 %–30 % of the SD_{a} in Miyako and Kashiwazaki, but it increased to over 50 % in Shizugawa, Hinase, and Ohno both for DO and pH. The $\text{maxSD}_{\text{m}}^{\text{a}}$ exceeded SD_{a} in Hinase and Ohno both for DO and pH. Even the $\text{maxSD}_{10}^{\text{a}}$ exceeded SD_{a} in Ohno in the case of DO, while it exceeded in Shizugawa, Hinase, and Ohno in the case of pH (Table 2). These results indicate that although the main driver of the annual variation for DO and pH were seasonal variation in Miyako and Kashiwazaki, shorter variation also contributed in Shizugawa, Hinase, and Ohno stations. In the case of Ω_{ar} , $\text{SD}_{\text{a(m)}}$ showed lower values than SD_{a} in all stations, indicating larger contribution of short-term variation compared with the case of DO and pH. The $\text{avgSD}_{\text{m}}^{\text{a}}$ was approximately half of SD_{a} for all stations, while the $\text{avgSD}_{10}^{\text{a}}$ was approximately one-third of the $\text{avgSD}_{\text{m}}^{\text{a}}$. Both $\text{maxSD}_{\text{m}}^{\text{a}}$ and $\text{maxSD}_{10}^{\text{a}}$ exceeded SD_{a} in most areas. These results indicate that short-term variation on the 10 d timescale is the significant driver of annual temporal variation for Ω_{ar} , which was similar to the case of salinity.

We further investigated the seasonal dependency of the 10 d SD in each area based on Table 3. The $\text{maxSD}_{10}^{\text{a}}$ for DO, pH_{min} , and Ω_{ar} occurred at approximately the same time, and moreover, seasonal distribution of $\text{avgSD}_{10}^{\text{a}}$ showed positive correlation with statistical significance ($r^2 > 0.5$) among these three parameters. These results indicate that the 10 d variations of these three parameters were caused by the same processes (i.e., biological activities).

However, the specific timing of the occurrence of the annual maximum for these three parameters differed among the areas. In Miyako, the annual maximum of $\text{avgSD}_{10}^{\text{a}}$ for DO, pH_{min} , and Ω_{ar} occurred in spring, when biological activities are the highest. In Shizugawa, Hinase, and Ohno, the maximum $\text{avgSD}_{10}^{\text{a}}$ for these parameters occurred during late summer and early autumn, which approximately overlapped with the timing of the occurrence of the annual maximum of $\text{avgSD}_{10}^{\text{a}}$ of salinity (Table 3). In Kashiwazaki, the maximum $\text{avgSD}_{10}^{\text{a}}$ for DO, pH_{min} , and Ω_{ar} occurred in winter, when strong perturbation of river flow induced by heavy snowfall caused an annual maximum $\text{avgSD}_{10}^{\text{a}}$ for both salinity and water temperature. Overall, the investigated statistical aspects of short-term variations indicated that several physical processes related to the 10 d salinity variation had derivatively induced biological processes that caused short-term variations in DO, pH_{min} , and Ω_{ar} in these coastal areas.

Temporal variation in pH and the related parameters are mainly analyzed with interannual, seasonal, and diurnal timescales (e.g., Bauman and Smith, 2018; Carstensen et al., 2019; Hassoun et al., 2017; Lowe et al., 2018; Provoost et al., 2010; Rosenau et al., 2021), but many studies have also highlighted the existence of significant day-to-day scale pH vari-

Table 2. Statistical aspects of environmental parameters in each station. Annual values are calculated based on the previous 1 year of data to avoid biases that come from different time lengths. See Appendix A for the abbreviation of each SDs with different timescales.

ation in coastal areas, especially in estuaries (e.g., Bednaršek et al., 2022; Frieder et al., 2012; Fujii et al., 2021; Hofmann et al., 2012; Johnson et al., 2013). The present results illustrated that such day-to-day variation with the timescales from 10 to 30 d contributes significantly to the annual variation in pH and the related parameters in the coastal areas of Japan. Indeed, the amplitude of SD_a and avgSD_m^a of pH_{min} observed in Hinase and Ohno was almost similar to those observed in US estuaries in previous studies (Bednaršek et al., 2022; Hofmann et al., 2012), indicating that such a significant contribution of short-term variation to total variability is common among the world’s estuaries. In several cites off California coasts, it was reported that eventual coastal upwelling brings carbon and nutrients to the coast and cause multi-day scale

pH variation (e.g., Frieder et al., 2012; Kessouri et al., 2021). On Japan’s coasts, on the other hand, the observed short-term variations in pH seemed to be connected strongly with that of salinity, suggesting that the change in riverine input plays a significant role in the short-term pH variation.

4.2 Classification of temporal variations into thermodynamic and non-thermodynamic components

To determine the processes that contribute to the short-term variation in biogeochemical properties, we divided the observed temporal variations of each parameter into thermodynamic and non-thermodynamic components using the fol-

Table 3. Monthly average of 10 d standard variation (avgSD_{10}^m) for each parameter in each month in each station. Numbers displayed in bold represent annual maximum and the second maximum.

lowing equation:

$$C_i = C_i(\text{eq}) + C_i(\text{diseq}), \quad (1)$$

where C_i represents the observed concentration of parameter i , $C_i(\text{eq})$ represents the estimated concentration of parameter i in equilibrium with the current atmosphere under the observed water temperature and salinity, and $C_i(\text{diseq})$ represents the difference between C_i and $C_i(\text{eq})$. This is the similar idea of AOU, while DO(diseq) is equivalent to AOU multiplied by -1 . For DO, DO(eq) was calculated from water temperature and salinity based on the formulation of Weiss (1970) with a fixed atmospheric pressure of 1 atm. Both pH(eq) and $\Omega_{\text{ar}}(\text{eq})$ were calculated using the CO2sys program with the same set of constants as described in Sect. 2.1, using water temperature, salinity, estimated TA, and a fixed atmospheric CO₂ mole fraction of 415 ppm.

Figure 11 shows the temporal variation in DO(eq), pH(eq), and $\Omega_{\text{ar}}(\text{eq})$, while Fig. 12 shows DO(diseq), pH_{min}(diseq),

and $\Omega_{\text{ar}}(\text{diseq})$. We also calculated 1-year SD, monthly SD, and 10 d SD for these parameters, and the results are listed in Table 4. The annual temporal variation was approximately the same between DO(eq) and DO(diseq) (Table 4), but their origin was significantly different. While seasonal variation played a dominant role in the temporal variation in DO(eq) (Fig. 11a; Table 4), short-term variations played a significant role in that of DO(diseq) (Fig. 12a; Table 4). In the case of pH, the temporal variation in pH(eq) resembles that of salinity (Figs. 7b and 11b), and the amplitude of pH(eq) (~ 0.25 ; Fig. 11b) was approximately one order smaller than that of pH(diseq) (~ 1.2 ; Fig. 12b). This result indicated that the thermodynamic process had a negligible contribution to the temporal variation in pH. Interestingly, the relative contributions of monthly SD and 10 d SD of pH(diseq) to the 1-year SD showed a similar structure to that of pH_{min} (Table 4), suggesting that the short-term variation at the scale of 10 d was the main driver of annual temporal variation for

Figure 11. Time series of (a) DO(eq), (b) pH(eq), and (c) $\Omega_{\text{ar}}(\text{eq})$ at the five stations. Legends of color plots are the same for all panels as shown in (b).

pH_{min}(diseq), which is similar to the cases of pH_{min} and salinity. Temporal variation in $\Omega_{\text{ar}}(\text{eq})$ had both seasonal- and short-term scale components (Table 4), and the pattern of seasonal variation resembled that of water temperature, while that of short-term variation resembled that of salinity (Fig. 11c). $\Omega_{\text{ar}}(\text{diseq})$ showed a similar scale of 1-year variability to that of $\Omega_{\text{ar}}(\text{eq})$ (Figs. 11c and 12c; Table 4), similar to the case of DO. The temporal pattern of $\Omega_{\text{ar}}(\text{diseq})$ was quite similar to that of pH_{min}(diseq), suggesting that short-term variation at the 10 d scale contributes significantly to the annual temporal variation in $\Omega_{\text{ar}}(\text{diseq})$, similar to the case of pH_{min}(diseq). Overall, the non-thermodynamic component contributed approximately half of the observed annual variation in DO and Ω_{ar} , and in the case of pH, the non-thermodynamic component played a dominant role in the annual variation. For all these biogeochemical parameters, the short-term variation at the 10 d scale contributed a significant percentage of the temporal variation in the non-thermodynamic component.

Figure 12. Time series of (a) DO(diseq), (b) pH_{min}(diseq), and (c) $\Omega_{\text{ar}}(\text{diseq})$ at the five stations. Legends of color plots are the same for all panels as shown in (a).

To determine the specific process that drives the non-thermodynamic temporal variation in these properties, we examined the correlation between pH_{min}(diseq) and DO(diseq) (Fig. 13a). These two properties showed significant positive correlation, indicating that the non-thermodynamic component of temporal variations was driven mainly by biological processes. Several studies have also detected a positive relationship between variations in oxygen saturation and the metabolic component of pH in coastal waters, suggesting the primary influence of biological processes on pH dynamics (e.g., Baumann and Smith, 2018; Lowe et al., 2019). We further investigated the correlation between DIC_{max}(diseq) and DO(diseq) (Fig. 13b); the former was calculated as pH_{min}(diseq) and $\Omega_{\text{ar}}(\text{diseq})$. Most data obtained in Miyako and Ohno, and approximately 50 % of data obtained in Shizugawa, approximately followed a linear regression line with the slope of $-\Delta\text{DIC}_{\text{max}}(\text{diseq})/\Delta\text{DO}(\text{diseq}) = 0.77 (\sim 106/138)$ crossing the origin, suggesting that the observed temporal variations of both DIC_{max}(diseq) and DO(diseq) were induced

by the production or decomposition of planktonic oceanic particles with C : O₂ ratio of 106 : 138 (Redfield et al., 1963) in these two areas. Such Redfield-type relationship between short-term variation in DO and that of DIC had also been observed in the coastal area of the East China Sea (Guo et al., 2021). The other data obtained in Shizugawa, as well as most data obtained in Hinase and Kashiwazaki, followed the regression lines with steeper slopes than that of open ocean stoichiometry.

The respiratory quotients of estuarine ecosystems can occasionally be as high as 1.5 (Wang et al., 2018) or even 2.0 (Giblin et al., 1997), when affected by the anaerobic respiration process in estuarine sediments. The observed high $-\Delta\text{DIC}_{\text{max}}(\text{diseq})/\Delta\text{DO}(\text{diseq})$ ratio thus suggests that lateral propagation of biological processes in the neighboring estuaries contributes significantly to the observed temporal variations of DIC_{max}(diseq) and DO(diseq) in these three areas. On the other hand, the turnover time of oxygen in ocean

Figure 13. Plot of (a) $\text{pH}_{\min}(\text{diseq})$ and (b) $\text{DIC}_{\max}(\text{diseq})$ against $\text{DO}(\text{diseq})$, respectively. The dashed purple line in (b) represents the theoretical line when assuming that biological production or degradation of organic matter occurs with the Redfield relationship ($-\Delta\text{pH}_{\min}(\text{diseq})/\Delta\text{DO}(\text{diseq}) = 106/138$). The dashed red line represents the regression line of Hinase data.

mixed layer due to air–sea gas exchange (in the range of several days to 2 weeks; Izett et al., 2018; Qin et al., 2021) is about 10 times shorter than that of CO_2 (of the order of several months; e.g., Jones et al., 2014), reflecting their abundance in seawater. The $\Delta\text{DO}(\text{diseq})$ that was once caused by biological processes therefore can recover to zero with shorter timescales than that of $\Delta\text{DIC}_{\max}(\text{diseq})$ through the air–sea gas exchange process. The observed difference in $-\Delta\text{DIC}_{\max}(\text{diseq})/\Delta\text{DO}(\text{diseq})$ ratio between Hinase and Ohno can also be explained by this mechanism, if large gas exchange processes (e.g., high wind speed and/or high wave height) have occurred in Hinase and not in Ohno. However, monthly-averaged wind speed was always higher in Ohno than in Hinase in the 2020 autumn (Japan Meteorological Agency weather record database; <https://www.data.jma.go.jp/stats/etrn/index.php>; last access: 5 January 2024), when low $\Delta\text{DO}(\text{diseq})$ and high $\Delta\text{DIC}_{\max}(\text{diseq})$ were mainly observed in this study (Fig. 12). Similarly, there is no significant difference in wind speed between two groups of Shizugawa data (one following Hinase data and the another following Ohno data). We thus conclude that relatively faster recovery of $\Delta\text{DO}(\text{diseq})$ compared with that of $\Delta\text{DIC}_{\max}(\text{diseq})$ through air–sea gas exchange is not the main cause of the observed high $-\Delta\text{DIC}_{\max}(\text{diseq})/\Delta\text{DO}(\text{diseq})$ ratio, although this process may partly contribute to create a high ratio in these areas.

4.3 Controlling factor of the amplitude of short-term pH variation

Our analyses in Sects. 3.2 and 3.4 clearly show that severe low pH/low Ω_{ar} situations occur only at the short-term pH drawdown events that coincide with rainfall events in the coastal areas of Japan (Figs. 9c and 10c). As the amplitude of pH variation related to rainfall events differed among the five coastal areas, it is important to understand the controlling factor that determines the amplitude of short-term pH variation. To investigate this aspect, we analyzed the relationship of statistical short-term variabilities between salinity and $\text{pH}_{\min}$. Since short-term variation mainly occurred on the timescale of < 10 d for both salinity and $\text{pH}_{\min}$ (see discussion in Sect. 4.1), we plotted the $\text{avgSD}_{10}^{\text{m}}$ of $\text{pH}_{\min}$ against that of salinity (Fig. 14). In this analysis, we introduced continuous monitoring data of pH and salinity obtained in Tokyo Bay (off Kawasaki artificial island; <https://www.tbeic.go.jp/MonitoringPost/manual/aboutObservedPoint02.pdf>; last access: 5 January 2024) to obtain information on highly eutrophic coastal areas. The details of the observation methods and the location settings of this station are described in Appendix B.

In Tokyo Bay, the $\text{avgSD}_{10}^{\text{m}}$ of $\text{pH}_{\min}$ (hereafter $\text{avgSD}_{10}^{\text{m}}(\text{pH})$) linearly increased with an increase in $\text{avgSD}_{10}^{\text{m}}$ of salinity ($\text{avgSD}_{10}^{\text{m}}(\text{sal})$; Fig. 14a), suggesting that freshwater transports the sources of biological processes (both organic carbon and dissolved nutrients) at a constant concentration regardless of the flow rate. On the other hand, in Hinase and Ohno, $\text{avgSD}_{10}^{\text{m}}(\text{pH})$ increased with that of $\text{avgSD}_{10}^{\text{m}}(\text{sal})$ at the same rate as observed in Tokyo Bay when $\text{avgSD}_{10}^{\text{m}}(\text{sal})$ was low but $\Delta\text{avgSD}_{10}^{\text{m}}(\text{pH})/\Delta\text{avgSD}_{10}^{\text{m}}(\text{sal})$ changed to a low value when $\text{avgSD}_{10}^{\text{m}}(\text{sal})$ exceeded 1.0 (Fig. 14b). Generally, suspended particle export of the river increases linearly with that of river discharge, while the percentage of particle organic materials (POM) within suspended particles decreases along with the increase in suspended particle export (e.g., Bukaveckas, 2022; Coynel et al., 2005; Point et al., 2007; Zhang et al., 2013). As a result, the increasing rate of the POM transport with that of river discharge tends to become weak when river discharge becomes high enough (Coynel et al., 2005; Kim et al., 2020). If we assume that short-term pH variation is mainly caused by

Figure 14. Plots $\text{avgSD}_{10}^m(\text{pH})$ against $\text{avgSD}_{10}^m(\text{sal})$ for (a) Tokyo Bay, (b) Hinase and Ohno, and (c) Miyako, Kashiwazaki, and Shizugawa, respectively. The dashed red line represents the regression line of Tokyo Bay and the dashed black lines represent that of (b) Hinase and Ohno, and (c) Miyako, Kashiwazaki, and Shizugawa, respectively. Dashed green and blue lines represent regression lines of Hinase and Ohno, and Miyako, Kashiwazaki, and Shizugawa, respectively, with the data of months with the $\text{avgSD}_{10}^m(\text{sal})$ higher than 1.0.

the degradation of POM discharged from rivers into coastal areas and subsequent biological production by using nutrients released from the degraded POM (e.g., Kubo et al., 2017; Salisbury et al., 2008; Tokoro et al., 2020), we can expect that $\Delta\text{avgSD}_{10}^m(\text{pH})/\Delta\text{avgSD}_{10}^m(\text{sal})$ will also become small in the months with high river discharge (i.e., high $\text{avgSD}_{10}^m(\text{sal})$). The observed result in this study also indicated that the concentration of biologically active materials transported by freshwater into the Seto Inland Sea was diluted at a high freshwater flow rate, while it was not diluted in the rivers flowing into Tokyo Bay, as the latter receives far higher anthropogenic nutrient loadings from its drainage basin than those received by the Seto Inland Sea. In the coastal area receiving further low anthropogenic nutrient loadings such as Miyako, Kashiwazaki, and Shizugawa, $\Delta\text{avgSD}_{10}^m(\text{pH})/\Delta\text{avgSD}_{10}^m(\text{sal})$ was much lower than that of Hinase and Ohno when $\text{avgSD}_{10}^m(\text{sal})$ exceeded 1.0 (Fig. 14c).

We determined the nutrient concentrations of the main freshwater sources for each of the three coastal area categories (i.e., respectively: Tashiro, Sabaishi, and Kitakami rivers for Miyako + Kashiwazaki + Shizugawa; Chikusa and Ohta rivers for Hinase + Ohno; and Ara, Tama, and Tsurumi rivers for Tokyo Bay) from the MOE Public Water Quality Database, and calculated the weighted mean nitrate concentration (NO_3) of river waters that flow into each coastal area using water transport as the weight. We then found that $\Delta\text{avgSD}_{10}^m(\text{pH})/\Delta\text{avgSD}_{10}^m(\text{sal})$ observed at high freshwater input (that is, $\text{avgSD}_{10}^m(\text{sal}) > 1.0$) showed a linear relationship with NO_3 in each coastal area category (Fig. 15). Even if we compare $\Delta\text{avgSD}_{10}^m(\text{pH})/\Delta\text{avgSD}_{10}^m(\text{sal})$ for all months, positive correlation against (NO_3) was still significant. These results imply that the amplitude of short-term variation in $\text{pH}_{\min}$ in coastal areas is principally determined by the quantity of nutrients transported by freshwater from the hinterland. However, we note that the riverine nitrate concentra-

Figure 15. Plot of $\Delta\text{avgSD}_{10}^m(\text{pH})/\Delta\text{avgSD}_{10}^m(\text{sal})$ against NO_3 for each coastal area category. The blue and red dots represent the slope calculated from all months and from the months with $\text{avgSD}_{10}^m(\text{sal})$ higher than 1.0, respectively. The dashed lines represent the regression lines.

tion can be an implicit function of other controlling factors. For example, we recently observed that the quantity of suspended organic particles in river waters, as well as accumulated organic materials in riverine and estuarine sediments, are linearly correlated with the riverine nitrate concentration (Tsuneo Ono, unpublished data). Hence, the NO_3 in Fig. 15 may actually be an indicator of the transport of these materials. We thus need further detailed observations, especially at the time of increase in water level of the river, to understand practical processes that cause short-term pH variation in coastal waters.

5 Conclusion

In this study, we synthesized data from continuous pH monitoring of five coastal areas in Japan from 2020 to 2021. Annual variability (~ 1 SD) of pH and Ω_{ar} were 0.05–0.09 pH units and 0.25–0.29, respectively, for three areas with low anthropogenic nutrient loadings (Miyako Bay, Kashiwazaki Coast, and Shizugawa Bay), while they increased to 0.16–0.21 pH units and 0.52–0.58, respectively, in two areas with medium anthropogenic nutrient loadings (Hinase Archipelago and Ohno Strait in Seto Inland Sea). Statistical assessment of temporal variability at various timescales revealed that most of the annual variabilities in both pH and Ω_{ar} were controlled by short-term variation with a timescale of < 10 d, rather than the seasonal-scale variation. Our analyses further illustrated that most of the short-term pH variation (and hence, annual variation) was caused by biological processes, while both thermodynamic and biological processes equally contributed to the temporal variation in Ω_{ar} . Biological alteration of pH mainly occurred in oceanic areas in Miyako Bay and Ohno Strait, whereas it occurred mainly in estuarine areas at Kashiwazaki Coast and Hinase Archipelago. In Shizugawa Bay, both oceanic and estuarine areas were responsible for the biological alteration of pH.

The observed results show that short-term acidification with Ω_{ar} of < 1.5 occurred occasionally in Miyako and Shizugawa bays, while it occurred frequently in the Hinase Archipelago and Ohno Strait. Many such short-term acidification events were related to short-term low-salinity events. Our analyses showed that the amplitude of short-term pH variation was linearly correlated with that of short-term salinity variation, and its regression coefficient at the time of high freshwater input was positively correlated with the nutrient concentration of the main river that flows into the coastal area.

Fortunately, no marine organism that has been damaged by ocean acidification has been detected in coastal areas of Japan (Fujii et al., 2023). However, our study showed that Ω_{ar} in Japanese coastal areas occasionally drops to a level that is potentially hazardous for marine organisms, such as Pacific oysters (< 1.5 ; Waldbusser et al., 2015), even in the present state. It is already known that the pH in Japanese coastal areas is decreasing at the same rate as that of the open ocean (Ishida et al., 2021; Ishizu et al., 2019), and hence, the extent, duration, and frequency of such short-term low pH and Ω_{ar} situations will increase in coastal areas in Japan in the future (Fujii et al., 2023). Our study indicates that the amplitude of the short-term drawdown of pH related to low-salinity events will decrease if we can reduce the nutrient concentration of rivers. Similar effects of anthropogenic nutrient reduction to diminish short-term Ω_{ar} drawdown in coastal waters are also reported by Kessouri et al. (2021). We note, however, that a certain percentage of Japanese coastal areas are now suffering due to the problem of low biological productivity derived from the decreased anthropogenic

nutrient input (e.g., Yamamoto et al., 2021). We must consider the balance between the risk of ocean acidification and oligotrophication when we control anthropogenic loadings to coastal waters in the future. We also note that not only the concentration of dissolved nutrients, but also other biologically active materials, such as suspended organic materials in river waters and accumulated organic materials in riverine and estuarine sediments, may be responsible for short-term pH variations at low-salinity events (e.g., Carstensen and Duarte, 2019; Salisbury et al., 2008). Our analysis revealed that seawaters in both the Hinase Archipelago and Ohno Strait were oversaturated with CO_2 all through the years, and hence, it is considered that more organic matter than that biologically produced within these areas was decomposed. In such cases, not only the reduction in dissolved nutrients but also the reduction in particulate organic matter transported from rivers to coastal areas will contribute to the suppression of short-term pH drawdown. Many studies have already mentioned the contribution of seaweed/seagrass beds to the effective capture of suspended organic sediments in estuaries (e.g., Barcelona et al., 2021; Leiva-Dueñas et al., 2023; Potouroglou et al., 2017), and hence, the conservation and/or development of seaweed/seagrass beds in estuarine and coastal areas will contribute to the reduction in organic matter transport from rivers to coastal areas at times of high river flow. To specify effective measures against the current coastal acidification in Japan, further detailed observations, especially at the time of increase in water level of the river, are needed such that we can obtain a detailed understanding of practical processes that cause short-term pH variation in coastal waters.

Appendix A: Abbreviations of standard deviations calculated in Sect. 4.1 at different timescales

SD_a	annual standard deviation of each data
$\text{SD}_{a(m)}$	annual standard deviation of monthly average
SD_m	monthly standard deviation of each data
avgSD_m^a	annual average of SD_m
maxSD_m^a	annual maximum of SD_m
SD_{10}	moving 10 d standard deviation of each data
avgSD_{10}^a	annual average of SD_{10}
maxSD_{10}^a	annual maximum of SD_{10}
avgSD_m^{10}	monthly average of SD_{10}

Figure A1. Schematic diagram of statistical products SD_a , $SD_{a(m)}$, SD_m , and SD_{10} . While only three SD_{10} s per month are presented in this diagram, we calculated each day's running SD_{10} by using ± 5 d data to further calculate $avgSD_{10}^m$.

Appendix B: Observation methods and location settings of Tokyo Bay data

Detailed data for Tokyo Bay (Kawasaki artificial island; Sect. 4.3), referred to herein, are described by the data holders at <https://www.tbeic.go.jp/MonitoringPost/manual/aboutObservedPoint02.pdf>; (last access: 5 January 2024). Here, we provide a brief summary.

Kawasaki artificial island (KAI) is located in the center of Tokyo Bay, the bay with the highest population in its basin area (2.9 million) and highest nutrient loadings (210 tN d^{-1}) in Japan. KAI is a huge concrete cylinder with a diameter of 200 m, in which an air vending system for the trans-bay free-way tunnel is stored. An autonomous ocean profiling system was set off KAI, which included a YSI 6600V2-4M multiple ocean sensor for the measurement of water temperature, salinity, and pH. The mechanical measurement resolution of the pH was ± 0.01 pH units. The sensors were cleaned and calibrated on a monthly basis. Although the pH sensor was calibrated against NBS buffers, we used pH data without conversion to a total scale, as we used these pH data only for the analysis of temporal variability. Vertical profiles were measured hourly, and the obtained data were distributed from the public database managed by the Tokyo Bay Environmental Information Center (<https://www.tbeic.go.jp/>)

MonitoringPost/ViewGraph/ViewGraph?buoyId=02; last access: 5 January 2024). We downloaded KAI data pertaining to July 2020 to December 2021 from this database and used them for analysis.

Data availability. Data from Tokyo Bay can be downloaded from the Tokyo Bay Environmental Information Center Public Database (<https://www.tbeic.go.jp/MonitoringPost/ViewGraph/ViewGraph?buoyId=02>, Tokyo Bay Environmental Information Center, 2024). Other data used in this study are provided in the Supplement.

Supplement. The supplement related to this article is available online at: <https://doi.org/10.5194/bg-21-177-2024-supplement>.

Author contributions. TOn and DM performed field measurements and water sampling at Miyako Bay. MH and MY performed field measurements and water sampling at Kashiwazaki Coast. AD performed field measurements and water sampling at Shizugawa Bay. SO, TT, MF, and RH performed field measurements and water sampling at Hinase Archipelago. TOk, GO, and KS performed field measurements and water sampling at Ohno Strait. TOn undertook the measurements of discrete carbonate samples taken at Miyako Bay and Kashiwazaki Coast, and MW undertook the measurements of those taken at Shizugawa Bay, Hinase Archipelago, and Ohno Strait. Analyses of data obtained by these efforts were performed by TOn.

Competing interests. The contact author has declared that none of the authors has any competing interests.
